What does a changing climate mean for the future of south Florida's wildlife?

Even floating minkies of the Everglades capture colorful images of alligators, panthers, ibises, and manatees. Over the centuries, we have familiarized ourselves with the assembly of animals that call this area home. But the world is changing, and so too are the species that call this area home. Global projections indicate south Florida will continue to contend with higher temperatures, drier conditions, and flooding as the world ahead (Anderson Devor et al. 2012). Recent modeling efforts shed new light on the potential outcomes due to temperature and precipitation changes may have for threatened and endangered species in the area.

Introduction

Climate plays an important role in the distribution of species. As the climate changes, species have responded with species migration and adaptation (Pearson and Dawson 2003). Among other and conservation practitioners can use "climate models" to predict the impacts of future environmental changes. These models describe the relative species occurrences and current climate (temperature patterns) using mathematical models that can be used to predict the likely climate in similar areas where climate in the similar to areas currently occur (Figure 1).

Climate envelope models fall within a larger model called species distribution models. These incorporate all types of environmental climatic variables, such as temperature, geology (from this point we will use SDMs), to refer to all models in this document. These environmental species occurrence data are the only input data required for SDMs. While acquiring and preparing these data is a straightforward procedure, scientists using SDMs

1. Choice of Contemporary Data

When using SDMs to determine relationships between the current climate, the first step is to determine the contemporary climate dataset. To determine SDMs for climate envelope datasets, we need two different climate datasets to build the model: (1) Climate Unit; <http://climate.usgs.gov/> and WorldClim; <http://www.worldclim.org/>. Both datasets (Clim and WorldClim) have been developed and use long-term weather station data (one data point per year) to create a complete set of average monthly temperature and precipitation data for each location that distinguishes them. However, the research groups that created them, and the datasets used, differ greatly in geographic coverage either, as shown in Figure 2.

Considerations for Building Climate-based Species Distribution Models

In this section, we will discuss the choice of data, the steps, and recommendations related to
